Abstract. Recommender systems attempt to find relevant data for their users. As the amount of data available in the Web becomes larger, this task becomes increasingly harder. In this paper we present a comparison of recommendation results when using different demographic features (age, location, gender, etc.) commonly available in online movie recommendation communities. We assume that demographic information holds implicit information about users taste and interests, and present results of a simple method that extends standard collaborative filtering algorithms to include one or several of these features. We evaluate the our assumption in movie recommendation scenario and combine different features in order to improve recommendation results.

Keywords: recommender systems, experimentation, human factors

1 Introduction

During the last 20 years, which constitutes the amount of time that recommender systems have been researched, the de facto standard has been Collaborative Filtering (CF). However, current systems contain much more information about users than their counterparts twenty years ago did. One type of information commonly available in current systems is the age, gender and location of the users. Research has shown that these and similar features are of importance when attempting to increase the quality of recommenders [3,4]. In this paper, we apply the implicit relation brought by these features in a movie recommendation scenario by a simple extension to the k-Nearest Neighbor algorithm and show that even a very simple approach utilizing this sort of data brings significant improvements in terms of recommendation quality.

1.1 Problem Statement and Contribution

In this paper, we evaluate how different demographic user features can be employed in order to improve the quality of recommendations in a movie recommendation scenario. It has been shown, that demographic data boost the quality of different information retrieval tasks. Weber and Castillo [4] used demographic information like average income, race, etc. to find difference between groups in
a search engine scenario. Said et al. [3] showed that different social groups have
difference in taste when it comes to movies as well.

In our work, we use a model that employs these features to create higher sim-
ilarity scores between users from the same demographic groups. We present first
results of experiments performed on a dataset containing demographic data. The
main contribution of this paper is a comparison of basic demographic features
and their effect on recommendation quality in a Collaborative Filtering-based
system.

2 Dataset and Experiments

In this paper, we use a dataset provided by Moviepilot\textsuperscript{1}, which is Germany’s
largest online movie recommendation community. The dataset has been previ-
ously described, analyzed and researched on numerous occasions [2]. The snap-
shot used in our experiments contains the ratings of 10,000 randomly selected
users who have rated at least one movie. In addition to the ratings, the dataset
also contains the age for 1,292 users, gender for 6,583 users and city for 4,400
users. Table 1a shows the percentage of ratings performed by the users for
which we have demographic data. The total number of ratings in our subset
is 1,539,393 spread over four years (2006 to 2010). The total number of ratings
in Moviepilot over the same amount of time is more than 7 million.

2.1 Experimental Setup

For the experiments, 50 training and evaluation sets each for every demographic
feature were created. The evaluation sets consist of 5000 ratings for 500 randomly
selected users. The selected users had to have at least 30 movies rated. Out
of these, 10 movies having been rated with a value above the user’s average
rating were extracted (i.e. the set of True Positive recommendations). The rest
of the data were used for training. For each of the demographic features (age,
city or gender), our recommender was run once with the similarity of users
with the same demographic properties multiplied, and once for users where the
assigned similarities solely based on their rating behavior. The multiplication
factor was set to 10,000 in order to significantly affect the similarity measure.
The recommendation algorithm used in our experiments was a slightly modified
version of the \textit{K-Nearest Neighbor} using the Pearson Correlation Coefficient as
the neighbor similarity measure. The results presented are the averages of all
runs.

2.2 Results

We evaluate the results with Mean Average Precision (MAP) and Precision
at 10. These measures were chosen since they are well-known and widely used
Table 1: Data statistics and results

The initial tests proved that our assumption, "demographic data has an impact on CF", is true. Gender, especially, seems to have a large impact with a resulting increase of 10% for MAP (and 22% Precision at 10) are very promising. Age seems, however, not to have a very high impact. This could be because the age property is currently describing a decade, i.e. born in the 70s, 80s, etc. We intend to treat age with a more dynamic approach using time slices (a window of +/- a number of years).

3 Conclusion and Future Work

Our early stage results show that demographic data does matter even in a movie recommendation scenario. We expect that finer grained data, similar to that used by Weber and Castillo [4] will most likely affect the quality of a recommender system even more. Our current work focuses on collecting and connecting this data to what we already have, as well as finding subgroups based on several features, i.e. age and city combined.
